Abstract

The paper presents an integrated view of the population structure and its role in establishing the ionization state of light elements in dynamic, finite density, laboratory and astrophysical plasmas. There are four main issues, the generalized collisional–radiative picture for metastables in dynamic plasmas with Maxwellian free electrons and its particularizing to light elements, the methods of bundling and projection for manipulating the population equations, the systematic production/use of state selective fundamental collision data in the metastable resolved picture to all levels for collisional–radiative modelling and the delivery of appropriate derived coefficients for experiment analysis. The ions of carbon, oxygen and neon are used in illustration. The practical implementation of the methods described here is part of the ADAS Project.

1. Introduction

The broad mechanism for radiation emission from a hot tenuous plasma is simple. Thermal kinetic energy of free electrons in the plasma is transferred by collisions to the internal energy of impurity ions,

$$\mathcal{A} + e \rightarrow \mathcal{A}^* + e, \quad (1)$$

where \mathcal{A}^* denotes an excited state and \mathcal{A} the ground state of the impurity ion. This energy is then radiated as spectrum line photons which escape from the plasma volume:

$$\mathcal{A}^* \rightarrow \mathcal{A} + h\nu, \quad (2)$$

where $h\bar{\nu}$ is the emitted photon energy and $\bar{\nu}$ its frequency. Similarly, ions in general increase or decrease their charge state by collisions with electrons:

where \mathcal{A}^+ denotes the next ionization stage of impurity ion \mathcal{A} . The situation is often referred to as the *coronal picture*. The coronal picture has been the basis for the description of impurities in fusion plasmas for many years. However, the progress towards ignition of fusion plasmas and to higher density plasmas requires a description beyond the coronal approximation. Models of finite density plasmas which include some parts of the competition between radiative and collisional processes are loosely called *collisional–radiative*. However, collisional–radiative theory in its origins (Bates *et al* 1962) was designed for the description of dynamic plasmas, and this aspect is essential for the present situations of divertors, heavy species, transport barriers and transient events. The present work is centred on *generalized collisional radiative* (GCR) theory (McWhirter and Summers 1984) which is developed in the following sections. It is shown that the consideration of relaxation time-scales, metastable states, secondary collisions etc—aspects rigorously specified in collisional–radiative theory—allow an atomic description suitable for modelling the newer areas above. The detailed quantitative description is complicated because of the need to evaluate individually the many controlling collisional and radiative processes, a task which is compounded by the variety of atoms and ions which participate. The focus is restricted to plasmas which are optically thin and not influenced by external radiation fields, and for which ground and metastable populations of ions dominate other excited ion populations. The paper provides an overview of key methods used to expedite this for light elements and draws illustrative results from the ions of carbon, oxygen and neon. The paper is intended as the first of a series of papers on the application of collisional–radiative modelling in more advanced plasma scenarios and to specific important species.

The practical implementation of the methods described here is part of the ADAS (atomic data and analysis structure) Project (Summers 1993, 2004). Illustrations are drawn from ADAS codes and the ADAS fundamental and derived databases.

1.1. Time constants

The lifetimes of the various states of atoms, ions and electrons in a plasma to radiative or collisional processes vary enormously. Of particular concern for spectroscopic studies of dynamic finite density plasmas are those of translational states of free electrons, atoms and ions and internal excited states (including states of ionization) of atoms and ions. These lifetimes determine the relaxation times of the various populations, the rank order of which, together with their values relative to observation times and plasma development times, determines the modelling approach. The key lifetimes divide into two groups. The first is the *intrinsic* group, comprising purely atomic parameters, and includes metastable radiative decay, τ_m , ordinary excited state radiative decay, τ_o , and auto-ionizing state decay (radiative and Auger), τ_a . The intrinsic group for a particular ion is generally ordered as

$$\tau_a \ll \tau_o \ll \tau_m\tag{4}$$

with typical values

$$\tau_m \sim 10^1/z^8 \text{ s}, \quad \tau_o \sim 10^{-8}/z^4 \text{ s}, \quad \tau_a \sim 10^{-13} \text{ s}.\tag{5}$$

where z is the ion charge. The second is the *extrinsic* group, which depends on plasma conditions—especially particle density. It includes free particle thermalization (including

electron–electron τ_{e-e} , ion–ion τ_{i-i} and ion–electron τ_{i-e} , charge-state change (ionization τ_{ion} and recombination τ_{rec}) and redistribution of population amongst excited ion states (τ_{red}). The extrinsic group is ordered in general as

$$\tau_{\text{ion,rec}} \gg \tau_{i-e} \gg \tau_{i-i} \gg \tau_{e-e} \quad (6)$$

with approximate expressions for the time constants given by

$$\begin{aligned} \tau_{\text{rec}} &\sim [10^{11} - 10^{13}](1/(z+1)^2)(kT_e/I_H)^{1/2}(\text{cm}^{-3}/N_e) \text{ s}, \\ \tau_{\text{ion}} &\sim [10^5 - 10^7](z+1)^4(I_H/kT_e)^{1/2}e^{\chi/kT_e}(\text{cm}^{-3}/N_e) \text{ s}, \\ \tau_{i-i} &\sim [7.0 \times 10^7](m_i/m_p)^{1/2}(kT_e/I_H)^{3/2}(1/z^4)(\text{cm}^{-3}/N_i) \text{ s}, \\ \tau_{i-e} &\sim [1.4 \times 10^9](m_i/m_p)^{1/2}((kT_e/I_H) + 5.4 \times 10^{-4}(kT_i/I_H)(m_p/m_i))^{3/2} \\ &\quad \times (1/z^2)(\text{cm}^{-3}/N_i) \text{ s}, \\ \tau_{e-e} &\sim [1.6 \times 10^6](kT_e/I_H)^{3/2}(\text{cm}^{-3}/N_i) \text{ s}. \end{aligned} \quad (7)$$

The ion mass is m_i , the proton mass m_p , the ionization potential χ , the ion density N_i , the electron density N_e , the ion temperature T_i , the electron temperature T_e and the ionization energy of hydrogen I_H . τ_{red} may span across the inequalities of equation (6) and is discussed in a later paragraph.

From a dynamic point of view, the intrinsic and extrinsic groups are to be compared with each other and with timescales, τ_{plasma} , representing plasma ion diffusion across temperature or density scale lengths, relaxation times of transient phenomena and observation times. For most plasmas in magnetic confinement fusion and astrophysics

$$\tau_{\text{plasma}} \sim \tau_g \sim \tau_m \gg \tau_o \gg \tau_{e-e}, \quad (8)$$

where τ_g represents the relaxation time of ground state populations of ions (a composite of τ_{rec} and τ_{ion}) and it is such plasmas which are addressed in this paper. These time-scales imply that the dominant populations of impurities in the plasma are those of the ground and metastable states of the various ions. The dominant populations evolve on time-scales of the order of plasma diffusion time-scales and so should be modelled dynamically, that is, in the time-dependent, spatially varying, particle number continuity equations, along with the momentum and energy equations of plasma transport theory. Illustrative results are shown in figure 1(a).

The excited populations of impurities and the free electrons on the other hand may be assumed to be relaxed with respect to the instantaneous dominant populations, that is, they are in *quasi-equilibrium*. The quasi-equilibrium is determined by local conditions of electron temperature and electron density. So, the atomic modelling may be partially de-coupled from the impurity transport problem into local calculations which provide quasi-equilibrium excited ion populations and emissivities and then effective source coefficients (collisional–radiative coefficients) for dominant populations which must be entered into the plasma transport equations. The solution of the transport equations establishes the spatial and temporal behaviour of the dominant populations which may then be re-associated with the local emissivity calculations for matching to and analysis of observations.

For excited populations, τ_{red} plays a special and complicated role due to the very large variation in collisional excitation/de-excitation reaction rates with the quantum numbers of the participating states. In the low density coronal picture $\tau_{\text{red}} \gg \tau_o$ and redistribution plays no part. Critical densities occur for $\tau_{\text{red}} \sim \tau_o$ and for $\tau_{\text{red}} \sim \tau_a$ and allow division of the (in principle) infinite number of excited populations into categories including *low levels*, *high singly excited levels* and *doubly excited levels* for which important simplifications are possible.

Figure 1. (a) Ratios of ground and metastable lifetimes to plasma timescales arising from the transport of some ions of nitrogen and neon at the edge of fusion plasmas. For N^0 the ground state to metastable state transfer time constant, τ_m , is contrasted with $\tau_v = \lambda_{sol}/v$ with typical scrape-off-layer thickness, $\lambda_{sol} \sim 2 \text{ cm}$, and $mv^2/2 \lesssim 1 \text{ eV}$ from chemical or physical sputtering and with $\tau_{dif} = \lambda_{sol}^2/D$ where a typical diffusion coefficient $D = 10^4 \text{ cm}^2 \text{ s}^{-1}$. For selected neon ions, $\tau_d = \lambda_{T_e, Ne}/v_{dif}$ is contrasted with the reciprocal of the sum of the inverses of the ionization and recombination time constants for the ground state. The latter illustrative results are for a JET-like tokamak H-mode radial plasma model with shaped diffusion and pinch terms. $T_e(r=0) = 1 \text{ keV}$ with a pedestal of 30 eV at $r = a$ and exponential decay (scale length = $0.01a$) in the scrape of layer at plasma minor radius, $a = 100 \text{ cm}$. v_{dif} combines pinch and concentration diffusion parts. (b) Critical densities, defined as $N_e(\tau_{red} = \tau_{0,a})$, for categories of excited populations of some oxygen ions. The x-axis scale for curve [1] is the orbital angular momentum, l , of the outer electron of doubly excited states; for curve [2] it is the principal quantum number, n , of the singly excited electron; for curve [3] it is a simple index to the three low-lying states illustrated. For low levels of ions, τ_{red} is markedly sensitive to the detailed atomic structure. $n = 3$ valence shells populations are of special relevance to the light element spectroscopy in the visible.

These are examined in section 2. Light element ions in fusion plasmas are generally in the singly excited state redistributive case, approaching the doubly excited redistribution case at higher densities. Highly ionized ions of heavy species in fusion plasmas approach the coronal picture. Illustrative results on critical densities are shown in figure 1(b).

Finally, because of the generally short τ_{e-e} compared with other timescales (including those of free–free and free–bound emission), it is usually the case that the free electrons have close to a Maxwellian distribution. This assumption is made throughout the present paper, but is relaxed in the next paper of the series (Bryans *et al* 2005).

1.2. Generalized collisional–radiative theory

The basic model was established by Bates *et al* (1962). The ion in a plasma is viewed as composed of a complete set of levels indexed by i and j and a set of radiative and collisional couplings between them denoted by C_{ij} (an element of the *collisional–radiative matrix* representing transition from j to i) to which are added direct ionizations from each level of the ion to the next ionization stage (coefficient S_i) and direct recombinations to each level of the ion from the next ionization stage (coefficient r_i). Thus, for each level, there is a total loss rate coefficient for its population number density, N_i , given by

$$-C_{ii} = \sum_{j \neq i} C_{ji} + N_e S_i. \quad (9)$$

Following the discussion in the introduction, it is noted that populated metastable states can exist, and there is no real distinction between them and ground states. We use the term *metastables* to denote both ground and metastable states. Metastables are the dominant populations and so only recombination events which start with a metastable as a collision partner matter. We consider the population structure of the z -times ionized ion, called the recombined or child ion. The $(z+1)$ -times ionized ion is called the recombining or parent ion and the $(z-1)$ -times ionized ion is called the grandchild. The metastables of the recombined ion are indexed by ρ and σ , those of the recombining ion by ν and ν' and those of the grandchild by μ and μ' . Therefore the ion of charge state z has metastable populations N_ρ , the recombining ion of charge $(z+1)$ has metastable populations N_ν^+ and the grandchild ion of charge $(z-1)$ has metastable populations N_μ^- . We designate the remaining excited states of the z -times ionized ion, with the metastables separated, as *ordinary* levels for which we reserve the indices i and j and populations N_i and N_j . There are then, for example, direct recombination coefficients, $r_{i,\nu}$, from each parent metastable into each child ordinary level and direct ionization coefficients from each child ordinary level to each parent metastable, $S_{\nu,i}$, such that $S_i = \sum_\nu S_{\nu,i}$. Also there are direct ionization coefficients, $S_{\rho,\mu'}$, to the metastables of the child from the metastables of the grandchild. Then the continuity equations for population number densities are

$$\frac{d}{dt} \begin{bmatrix} N_\mu^- \\ N_\rho \\ N_i \\ N_\nu^+ \end{bmatrix} = \begin{bmatrix} C_{\mu\mu'} & N_e \mathcal{R}_{\mu,\sigma} & 0 & 0 \\ N_e S_{\rho\mu'} & C_{\rho\sigma} & C_{\rho j} & N_e r_{\rho\nu'} \\ 0 & C_{i\sigma} & C_{ij} & N_e r_{i\nu'} \\ 0 & N_e S_{\nu\sigma} & N_e S_{\nu j} & C_{\nu\nu'} \end{bmatrix} \begin{bmatrix} N_\mu^- \\ N_\sigma \\ N_j \\ N_{\nu'}^+ \end{bmatrix}, \quad (10)$$

where the equations for the $(z-1)$ -times and $(z+1)$ -times ionized ions have been simplified by incorporating their ordinary population contributions in their metastable contributions (shown as script capital symbols) as the immediate focus is on the z -times ionized ion. This incorporation procedure is shown explicitly in the following equations for the z -times ionized ion through to equation (16) and may be done for each ionization stage separately. Note additionally the assumption (made by omission of the (3,1) partition element, where 3 denotes the row and 1 the column) that state-selective ionization from the stage $(z-1)$ takes place only into the metastable manifold of the stage z .

1.2.1. *Derived source term coefficients.* From the quasi-static assumption, we set $dN_i/dt = 0$, and then the matrix equation for the ordinary levels of the z -times ionized ion gives

$$N_j = -C_{ji}^{-1} C_{i\sigma} N_\sigma - N_e C_{ji}^{-1} r_{iv'} N_{v'}^+, \quad (11)$$

where we have used summation convention on repeated indices. Substitution in equation (10) for the metastables of the z -times ionized ion gives

$$\frac{dN_\rho}{dt} = N_e [S_{\rho\mu'}] N_{\mu'}^- + [C_{\rho\sigma} - C_{\rho j} C_{ji}^{-1} C_{i\sigma}] N_\sigma + N_e [r_{\rho v'} - C_{\rho j} C_{ji}^{-1} r_{iv'}] N_{v'}^+. \quad (12)$$

The left-hand side is interpreted as a total derivative with time-dependent and convective parts and the right-hand side comprises the source terms. The terms in square brackets in equation (12) give the effective growth rates of each metastable population of the z -times ionized ion driven by excitation (or de-excitation) from other metastables of the z -times ionized ion, by ionization to the $(z+1)$ -times ionized ion and excitation to other metastables of the z -times ionized ion (a negatively signed growth) and by recombination from the metastables of the $(z+1)$ -times ionized ion. These are called the GCR coefficients. Following Burgess and Summers (1969), who used the name ‘collisional–dielectronic’ for ‘collisional–radiative’ when dielectronic recombination is active, we use the nomenclature ACD for the GCR recombination coefficients which become

$$\text{ACD}_{v \rightarrow \rho} \equiv \mathcal{R}_{\rho v} = r_{\rho v} - C_{\rho j} C_{ji}^{-1} r_{iv}. \quad (13)$$

The GCR metastable cross-coupling coefficients (for $\rho \neq \sigma$) are

$$\text{QCD}_{\sigma \rightarrow \rho} \equiv C_{\rho\sigma} / N_e = [C_{\rho\sigma} - C_{\rho j} C_{ji}^{-1} C_{i\sigma}] / N_e. \quad (14)$$

Note that the on-diagonal element $[C_{\rho\sigma} - C_{\rho j} C_{ji}^{-1} C_{i\sigma}] / N_e$ with $\sigma = \rho$ is a total loss rate coefficient from the metastable ρ . Substitution of equation (11) in equation (10) for metastables of the $z+1$ -times ionized ion gives

$$\frac{dN_v^+}{dt} = N_e [S_{v\sigma} - S_{vj} C_{ji}^{-1} C_{i\sigma}] N_\sigma + [C_{vv'} - N_e^2 S_{vj} C_{ji}^{-1} r_{iv'}] N_{v'}^+. \quad (15)$$

The GCR ionization coefficients resolved by initial and final metastable states are

$$\text{SCD}_{\sigma \rightarrow v} \equiv S_{v\sigma} = [S_{v\sigma} - S_{vj} C_{ji}^{-1} C_{i\sigma}], \quad (16)$$

and note that there is a contribution to cross-coupling between parents via recombination to excited states of the z -times ionized ion followed by re-ionization to a different metastable,

$$\text{XCD}_{v' \rightarrow v} = -N_e [S_{vj} C_{ji}^{-1} r_{iv'}]. \quad (17)$$

Consider the sub-matrix comprising the (2,2), (2,3), (3,2) and (3,3) partitions of equation (10). Introduce the inverse of this sub-matrix as

$$\begin{bmatrix} W_{\rho\sigma} & W_{\rho j} \\ W_{i\sigma} & W_{ij} \end{bmatrix} = \begin{bmatrix} C_{\rho\sigma} & C_{\rho j} \\ C_{i\sigma} & C_{ij} \end{bmatrix}^{-1}, \quad (18)$$

and note that the inverse of the (1,1) partition

$$[W_{\rho\sigma}]^{-1} \equiv C_{\rho\sigma} = [C_{\rho\sigma} - C_{\rho j} C_{ji}^{-1} C_{i\sigma}]. \quad (19)$$

This compact representation illustrates that the imposition of the quasi-static assumption leading to elimination of the ordinary level populations in favour of the metastable populations may be viewed as a *condensation* in which the influence of the ordinary levels is *projected* onto the metastable levels. The metastables can be condensed in a similar manner onto the ground restoring the original (ground states only) collisional–radiative picture. The additive character of the direct metastable couplings, $C_{\rho\sigma}$, means that these elements may be adjusted retrospectively after the main condensations.

1.2.2. Derived emission and power coefficients. There are two kinds of derived coefficients associated with individual spectrum line emission in common use in fusion plasma diagnosis. These are *photon emissivity coefficients* (PECs) and *ionization per photon ratio* (SXB). The reciprocals of the latter are also known as *photon efficiencies*. From equation (11), the emissivity in the spectrum line $j \rightarrow k$ may be written as

$$\epsilon_{j \rightarrow k} == A_{j \rightarrow k} N_e N_j = A_{j \rightarrow k} \left(\sum_{\sigma} \mathcal{F}_{j\sigma}^{(\text{exc})} N_e N_{\sigma} + \sum_{v'=1}^M \mathcal{F}_{jv'}^{(\text{rec})} N_e N_{v'}^+ \right). \quad (20)$$

This allows specification of the *excitation* photon emissivity coefficient

$$\text{PEC}_{\sigma, j \rightarrow k}^{(\text{exc})} = A_{j \rightarrow k} \mathcal{F}_{j\sigma}^{(\text{exc})} \quad (21)$$

and the *recombination* photon emissivity coefficient

$$\text{PEC}_{v', j \rightarrow k}^{(\text{rec})} = A_{j \rightarrow k} \mathcal{F}_{jv'}^{(\text{rec})}. \quad (22)$$

The ionization per photon ratios are most meaningful for the excitation part of the emissivity and are

$$\text{SXB}_{\sigma, j \rightarrow k}^{(\text{ion})} = \sum_{v=1}^{M_z-1} \text{SCD}_{\sigma \rightarrow v} / A_{j \rightarrow k} \mathcal{F}_{j\sigma}^{(\text{exc})}. \quad (23)$$

Each of these coefficients is associated with a particular metastable σ , v' or μ' of the A^{+z} , A^{+z+1} or A^{+z-1} ions, respectively.

The radiated power in a similar manner separates into parts driven by excitation and by recombination as

$$\text{PLT}_{\sigma} = \sum_{j,k} \Delta E_{j \rightarrow k} A_{j \rightarrow k} \mathcal{F}_{j\sigma}^{(\text{exc})} \quad (24)$$

called the *low-level line power coefficient* and

$$\text{PRB}_{v'} = \sum_{j,k} \Delta E_{j \rightarrow k} A_{j \rightarrow k} \mathcal{F}_{jv'}^{(\text{rec})} \quad (25)$$

called the *recombination-bremsstrahlung power coefficient* where it is convenient to include bremsstrahlung with PRB. Note that in the generalized picture, additional power for the z -times ionized ions occurs in forbidden transitions between metastables as

$$\sum_{\rho, \sigma} \Delta E_{\sigma \rightarrow \rho} A_{\sigma \rightarrow \rho} N_{\sigma} \quad (26)$$

for the z -times ionized ion. In the fusion context, this is usually small. Radiated power is the most relevant quantity for experimental detection. For modelling, it is the *electron energy loss function* which enters the fluid energy equation. The contribution to the total electron energy loss rate for the z -times ionized ion associated with ionization and recombination from the $(z+1)$ -times ionized ion is

$$\begin{aligned} & \sum_{\rho} E_{\rho} \left(\sum_{\sigma} C_{\rho\sigma} N_{\sigma} + N_e \sum_{v'} \mathcal{R}_{\rho v'} N_{v'} \right) + \sum_{v} E_v \left(\sum_{\sigma} S_{v\sigma} N_{\sigma} + N_e \sum_{v'} C_{vv'} N_{v'} \right) \\ & + \sum_{\rho, \sigma} \Delta E_{\sigma \rightarrow \rho} A_{\sigma \rightarrow \rho} N_{\sigma} + \sum_{\sigma} \text{PLT}_{\sigma} N_e N_{\sigma} + \sum_{v'} \text{PRB}_{v'} N_e N_{v'}, \end{aligned} \quad (27)$$

where E_{ρ} and E_v are absolute energies of the metastables ρ of the z -times ionized ion and of the metastables v of the $(z+1)$ -times ionized ion, respectively. Thus the electron energy loss is a derived quantity from the radiative power coefficients and the other generalized

collisional–radiative coefficients. Note that cancellations in the summations cause reduction to relative energies and that in ionization equilibrium, the electron energy loss equals the radiative power loss.

In the following sections, it is shown how the quasi-static assumption and population categorization allow us to solve the infinite level population structure of each ion in a manageable and efficient way. Such a solution is necessary for low and medium density astrophysical and magnetic confinement fusion plasmas. This is unlike the simpler situation of very dense plasmas where heavy level truncation is used, because of continuum merging.

2. Excited population structure

The handling of metastables in a generalized collisional–radiative framework requires a detailed specific classification of level structure compatible with both recombining and recombined ions. For light element ions, Russell–Saunders (L–S) coupling is appropriate and it is sufficient to consider only terms, since although fine structure energy separations may be required for high resolution spectroscopy, relative populations of levels of a term are close to statistical. So the parent ion metastables are of the form $\gamma_v L_v S_v$ with γ_v the configuration, and the recombined ion metastables are of the form $\Gamma_\rho L_\rho S_\rho$ with the configuration $\Gamma_\rho = \gamma_v + n_i l_i$ and the excited (including highly excited) terms are $(\gamma_v L_v S_v) n_i l_i L_i S_i$. n and l denote individual electron principal quantum number and orbital angular momentum, L and S denote total orbital and total spin angular momenta of the multi-electron ion, respectively, in the specification of an ion state in Russell–Saunders coupling. The configuration specifies the orbital occupancies of the ion state. For ions of heavy elements, relative populations of fine structure levels can differ markedly from statistical, and it is necessary to work in intermediate coupling with parent metastables of the form $\gamma_v J_v$ and recombined metastables of the form $\Gamma_\rho J_\rho$ with the configuration $\Gamma_\rho = \gamma_v + n_i l_i$ and the excited (including highly excited) levels $(\gamma_v J_v) n_i l_i j_i J_i$. There is a problem. To cope with the very many principal quantum shells participating in the calculations of collisional–dielectronic coefficients at finite density necessitates a grosser viewpoint (in which populations are *bundled*), whereas for modelling detailed spectral line emission, a finer viewpoint (in which populations are fully *resolved*) is required. In practice, each ion tends to have a limited set of low levels principally responsible for the dominant spectrum line power emission for which a bundled approach is too imprecise, that is, averaged energies, oscillator strengths and collision strengths do not provide a good representation. Note also that key parent transitions for dielectronic recombination span a few (generally the same) low levels for which precise atomic data are necessary. In the recombined ion, parentage gives approximate quantum numbers, that is, levels of the same n (and l) divide into those based on different parents. Lifetimes of levels of the same n but different parents can vary strongly (e.g. through secondary autoionization). Also the recombination population of such levels is generally from the parent with which they are classified. We therefore recognize three sets of non-exclusive levels of the recombined ion:

- (i) metastable levels—indexed by ρ, σ ;
- (ii) low levels—indexed by i, j in a resolved coupling scheme, being the complete set of levels of a principal quantum shell range $n : n_0 \leq n \leq n_1$, including relevant metastables and spanning transitions contributing substantially to radiative power or of interest for specific observations;
- (iii) bundled levels—segregated according to the parent metastable upon which they are built and possibly also by spin system—which can include *bundle-nl* and *bundle-n*.

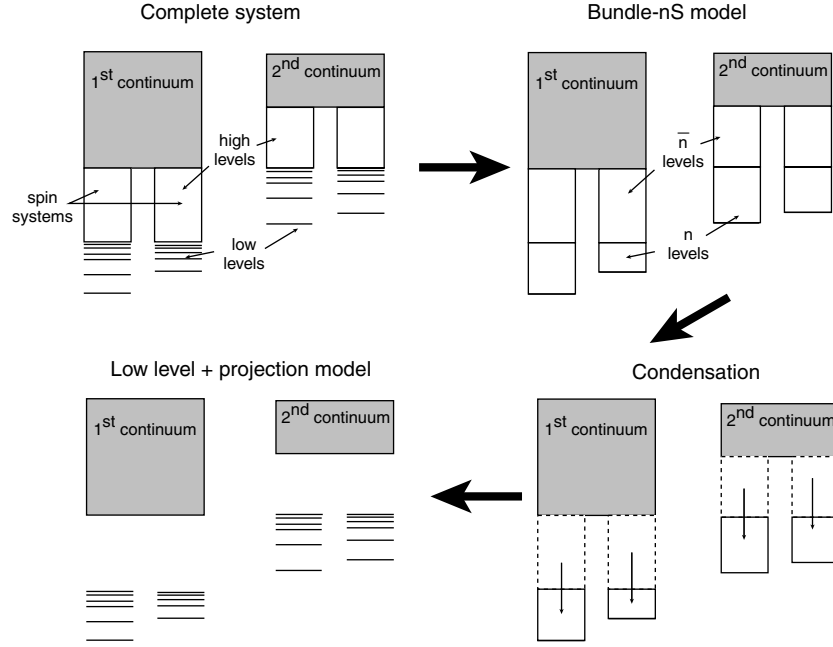

Figure 2. Schematic of population modelling and condensation procedures. It represents two metastable parent states of non-zero spin, so that when an nl electron is added, each yields two spin systems for the z -times ionized ion.

Viewed as a recombining ion, the set (i) must include relevant parents and set (ii) must span transitions which are dielectronic parent transitions. Time dependence matters only for the populations of (i), high precision matters only for groups (i) and (ii) and special very many level handling techniques matter only for group (iii).

To satisfy the various requirements and to allow linking of population sets at different resolutions, a series of manipulations on the collisional–radiative matrices are performed (Summers and Hooper 1983). To illustrate this, suppose there is a single parent metastable state. Consider the collisional–radiative matrix for the recombined ion and the right-hand side in the bundle- n picture and a partition of the populations as $[n, \bar{n}]$ with $n : n_0 \leq n \leq n_1$ and $\bar{n} : n_1 \leq \bar{n}$. Elimination of the $N_{\bar{n}}$ yields a set of equations for the N_n . We call this a ‘condensation’ of the whole set of populations onto the n populations. The coefficients are the effective ionization coefficients from the n , the effective cross-coupling coefficients between the n and the effective recombination coefficients into the n , which now include direct parts and indirect parts through the levels \bar{n} . Exclusion of the direct terms prior to the manipulations yields only the indirect parts. Call these $C_{nn'}^{\text{indir}}$ and r_{nv}^{indir} . We make the assumption that $C_{nn'}^{\text{indir}}$ and r_{nv}^{indir} may be expanded over the resolved low level set (see section 2.2) to give the expanded indirect matrix C_{ij}^{indir} and r_{iv}^{indir} where i and j span the resolved low level set (ij). These indirect couplings are then combined with higher precision direct couplings C_{ij}^{dir} and r_{iv}^{dir} so that

$$C_{ij} = C_{ij}^{\text{dir}} + C_{ij}^{\text{indir}} \quad (28)$$

and

$$r_{iv} = r_{iv}^{\text{dir}} + r_{iv}^{\text{indir}}. \quad (29)$$

The procedure is shown schematically in figure 2. The process may be continued, condensing the low level set onto the metastable set. The generalized collisional–dielectronic coefficients are the result. The time dependent and/or spatial non-equilibrium transport equations which describe the evolution of the ground and metastable populations of ions in a plasma use these generalized coefficients. Following the solution, the condensations can be reversed to recover the complete set of excited populations and, hence, any required spectral emission. The progressive condensation described above can be viewed simply as one of a number of possible paths which might be preferred because of special physical conditions or observations.

For light element ions, four types of bundling and condensation are distinguished in this work:

- (a) ground parent, spin summed bundle- $n \rightarrow$ lowest n -shell;
- (b) parent and spin separated bundle- $n \rightarrow$ lowest spin system n -shell (the *bundle- nS population model*);
- (c) low LS resolved \rightarrow metastable states (the *low-level population model*);
- (d) parent and spin separated bundle- $n \rightarrow$ low LS resolved \rightarrow metastable states.

Type (a) corresponds to the approach used in Summers (1974). Type (c) corresponds to the usual population calculation for low levels in which (consistent) recombination and ionization involving excited states are ignored. It establishes the dependence of each population on excitation for various metastables only. Type (d), effectively the merging of (b) and (c) in the manner described earlier, is the principal procedure to be exploited in this work for first quality studies. Details are in the following subsections.

2.1. The bundle- nS model

Now let \mathcal{A}^{+z_1} denote the recombining ion and \mathcal{A}^{+z_1-1} the recombined ion so that $z = z_1 - 1$ is the ion charge of the latter. z_1 is the effective ion charge and takes the place of the nuclear charge in the reduction of hydrogenic rate coefficients to compact forms in the statistical balance equations. Also introduce bundled populations

$$N_{v,nS} \equiv N_{(\gamma_v L_v S_v),nS} = \sum_{l,L} N_{(\gamma_v L_v S_v),nlLS} \quad (30)$$

and the assumption that

$$N_{v,nlLS} = \frac{(2L+1)}{(2l+1)(2L_v+1)} N_{v,nS} = \frac{(2L+1)}{n^2(2L_v+1)} N_{v,nS}. \quad (31)$$

The bundling is based on the observation that the largest collision cross-sections are those for which $n = n'$ and $l = l' \pm 1$. For these cases the transition energy is small (effectively zero for hydrogen or hydrogenic ions) and the cross-sections are so large for electron densities of relevance for fusion that it is a very good approximation to assume relative statistical population for the lL sub-states. The assumption is weakest for populations of states with core penetrating valence electron orbitals and we expect spin system breakdown for high nl states progressively at lower n and l for increasing ion charge z . Thus the above assumptions are appropriate for light element ions with a more elaborate *bundle- $(J_p)nlj$* model more suited to heavy element ions. The latter will be the subject of a separate paper. In the bundle- nS model, only equilibrium populations of complete n -shells for a given parent and spin system need be evaluated, which

are the solutions of the statistical balance equations

$$\begin{aligned}
& \sum_{n'=n+1}^{\infty} [A_{n' \rightarrow n} + N_e q_{n' \rightarrow n}^{(e)} + N_p q_{n' \rightarrow n}^{(p)}] N_{v,n'S} + \sum_{n''=n_0}^{n-1} [N_e q_{n'' \rightarrow n}^{(e)} + N_p q_{n'' \rightarrow n}^{(p)}] N_{v,n''S} \\
& + \omega_{S_v,S} [N_e N_v^+ \alpha_n^{(r)} + N_e N_v^+ \alpha_n^{(d)} + N_e^2 N_v^+ \alpha_n^{(3)}] \\
& = \left\{ \sum_{n'=n+1}^{\infty} [N_e q_{n \rightarrow n'}^{(e)} + N_p q_{n \rightarrow n'}^{(p)}] + \sum_{n''=n_0}^{n-1} [A_{n \rightarrow n''} + N_e q_{n \rightarrow n''}^{(e)} + N_p q_{n \rightarrow n''}^{(p)}] \right. \\
& \quad \left. + N_e q_{n \rightarrow \epsilon}^{(e)} + N_e q_{n \rightarrow \epsilon}^{(p)} + \sum_{v'} A_{v,nS \rightarrow v'}^a \right\} N_{v,nS}. \tag{32}
\end{aligned}$$

N_v^+ is the population of the parent ion $\mathcal{A}_v^{+z_1}$, N_e is the free electron density and N_p the free proton density, A is the usual Einstein coefficient, $q^{(e)}$ and $q^{(p)}$ denote collisional rate coefficients due to electrons and protons, $\alpha_n^{(r)}$, $\alpha_n^{(d)}$ and $\alpha_n^{(3)}$ denote radiative, dielectronic and three-body recombination coefficients, respectively, $A_{v,nS \rightarrow v'}^a$ denotes secondary autoionization and $q_{n \rightarrow \epsilon}^{(e)}$ and $q_{n \rightarrow \epsilon}^{(p)}$ denote collisional ionization rate coefficients due to electrons and protons, respectively, and $\omega_{S_v,S}$ is a spin weight factor (see equation (33) below). For complex ions, there are separate systems of equations for each parent and for up to two spin systems (in L-S coupling) built on each parent and one such equation for each value of n from the lowest allowed n -shell n_0 for the parent/spin system to ∞ . The number of spin systems is labelled N_{sys} and the lowest allowed n -shell $n_0 = n_0^{(r)}$, the lowest accessible shell by recombination except for doublets built on the He-like $1s2s\ ^3S$ parent. In general bare nuclei of other elements are effective ion projectiles along with protons. We use the word protons here to represent mean z_{eff} ions with suitably scaled collisional rate coefficients. These equations are analogous to the equations for hydrogen, and coupling-independent expressions may be used for the main $n \rightarrow n'$ coefficients provided a suitable spin system weight factor

$$\omega_{S_v,S} = \frac{(2S+1)}{2(2S_v+1)} \tag{33}$$

is introduced. Table 1 summarises these various parameters for first period iso-electronic sequences up to fluorine/neon. There are a number of issues.

2.1.1. b -factors and lowest levels. For hydrogenic ions it was advantageous to write the statistical equations in terms of Saha-Boltzmann deviation factors. This remains true for complex ions but the definition must be generalized. The deviation $b_{v,nS}$ is defined by

$$N_{v,nS} = N_e N_v^+ 8 \left(\frac{\pi a_0^2 I_H}{k T_e} \right)^{3/2} \frac{\omega_{v,nS}}{2\omega_v} \exp(I_{v,nS}/k T_e) b_{v,nS}. \tag{34}$$

That is, $b_{v,nS}$ is specified with respect to the parent ion state $\mathcal{A}_v^{+z_1}$, and the ionization potential $I_{v,nS}$ is also referred to that parent. a_0 is the Bohr radius. Note that $\omega_{v,nS} = \omega_{S_v,S} n^2 \omega_v$ where $\omega_v = (2S_v+1)(2L_v+1)$ is the parent statistical weight. It is convenient to introduce $c_{v,nS} = b_{v,nS} - 1$ and scaled temperatures and densities

$$\begin{aligned}
\theta_e &= \left(\frac{k T_e}{I_H} \right) \frac{1}{z_1^2}, \\
\rho_e &= 2^5 \sqrt{\frac{\pi}{3}} \frac{\pi a_0^3 N_e}{\alpha^3 z_1^7}, \tag{35}
\end{aligned}$$

with similar forms for the proton temperature and density. α is the fine structure constant. In these terms the statistical balance equations become particularly suitable for calculation, and

Table 1. Bundle- nS calculation pathways. The parent/spin system weight factor is defined in equations (32) and (33). N_{met} indicates the number of metastables of the recombined ion associated with the parent/spin system. The *parent index*, sequentially numbering the different parents shown in brackets, is used as the reference for tabulation of coefficients.

Rec. seq	Parent index	Parent/spin system	$\omega_{S_v, S}$	Lowest metastable	N_{met}
H-like	1	$(1s^2 S)^1 n$	0.250	$1s^2^1 S$	1
		$(1s^2 S)^3 n$	0.750	$1s2s^3 S$	1

resulting GCR coefficients (z -scaled), on a θ_e/ρ_e grid, can sustain interpolation of moderate precision within an iso-electronic sequence.

The parent/spin system model does not distinguish recombined metastables within the same spin system. For example, consider the $2s^2 2p^2 P$ parent in a B-like like ion recombining into the singlet system of the C-like ion. The parent/spin system has two metastables, $2s^2 2p^2^1 D$ and $2s^2 2p^2^1 S$. We assign the effective ground state as the lowest energy metastable ($2s^2 2p^2^1 D$ state in this example) and assign statistically weighted n -shell sub-populations to resolve between the recombined metastables. There is often a substantial difference between the quantum defect of the lowest state itself and the mean quantum defect arising from a weighted average of the lowest n -shell terms. These choices improve the stepwise part of the collisional–radiative ionization coefficient within the bundle- nS picture at low density and allow the bundle- nS model to stand alone, albeit at some reduction in accuracy. A precise solution, as adopted in this paper, is given by the condensation/projection/expansion matrix transfer of the bundle- nS model onto the low level solution which distinguishes

explicitly between the LS terms in the lowest few quantum shells from the beginning (see section 2.2).

2.1.2. Auto-ionization and alternate parents. Let the metastable state which represents the lowest level of recombined parent/spin system ν, nS be labelled by ρ . With parent ν , from a stepwise collisional–radiative point of view, it is convenient to refer to ν, nS as an intermediate state system and label it $(\nu) (2S+1)n$. Thus a recombination/stepwise/cascade pathway may progress from a parent ν through the intermediate state ν, nS ending on the metastable ρ with the effective GCR recombination coefficient written as $ACD_{\nu \rightarrow (\nu) (2S+1)n; \rho}$ and likewise a stepwise excitation/ionization pathway may progress from the lowest metastable ρ via the intermediate state ν, nS to the final ionized ion metastable ν with the effective GCR ionization coefficient $SCD_{\rho \rightarrow (\nu) (2S+1)n; \nu}$. The population calculation for a given pathway involves the excited state population structure connecting the recombining parent ν and the metastable ρ . However, an alternative parent, which is not the intermediate state parent, can be populated by autoionization of excited states above the auto-ionization threshold. That is, if the parent ν is a metastable there exists a lower lying ground state (or possibly other metastable) of the parent, say ν' . The excited state populations of the ν, nS system must include such auto-ionization processes. Above the auto-ionization threshold, and at low electron densities, auto-ionization is the dominant loss mechanism. However, the bundle- n auto-ionization transition probabilities scale as n^{-5} and are independent of electron density, whereas direct ionization loss rates scale as n^4 and vary directly with electron density. For high n -shells, direct ionization is the dominant loss process. As the electron density increases, direct ionization becomes the dominant loss process for all n -shells and auto-ionization is quenched. The inclusion of auto-ionization transition probabilities in the statistical balance equations leads to dramatic changes in the population structure as shown in figures 3(a) and (b). In the example, the populations of $C^{+1}(2s^2 \ ^1S) \ ^2n$ are built upon a ground state parent, so no auto-ionization pathways are accessible from the excited states. If the populations are expressed in terms of the Saha–Boltzmann b -factors then they show strong overpopulation of the high n -shells at low electron density due to dielectronic recombination. As the electron density is increased, the dielectronic recombination influence becomes less due to ionization of the high n -shell populations with all the b -factors tending to 1. This behaviour is typical for a recombined system built on a ground state parent. By contrast, the populations of $C^{+1}(2s2p \ ^3P) \ ^2n$, built upon an excited metastable parent, show powerful depopulation above the auto-ionization threshold. As the electron density increases, the direct ionizing collisions from the excited states compete more strongly and the b -factors tend to 1.

The definitions of generalized collisional–radiative ionization and recombination coefficients are still relevant but give the recombination rate from ν to ρ and the total loss rate from ρ (i.e. with no resolution of final parent after ionization), respectively. The recombination coefficient is already correctly parent/metastable resolved and needs no further adjustment. The correct parent resolved (partial) ionization coefficients, $SCD_{\rho \rightarrow (\nu) (2S+1)n; \nu'}$, are derived by constructing the loss vector from each level. Because the model considers the excited state populations, $N_{\nu, nS}$, direct ionization only populates $A_{\nu}^{+z_1}$. The alternative parents are populated by auto-ionization. The parent resolved loss vectors are thus given by

$$\begin{aligned} L_{\nu, nS \rightarrow \nu} &= N_e q_{\nu, nS \rightarrow \nu}, \\ L_{\nu, nS \rightarrow \nu'} &= A_{\nu, nS \rightarrow \nu'}^a. \end{aligned} \quad (36)$$

Ionization pathways and the expected (partial) GCR ionization coefficients for $C^{+1} + e \rightarrow C^{+2} + e + e$ are summarized in table 2. From the point of view of recombination from ν via intermediate states ν, nS towards ρ , autoionization allows exit into the alternative parent ν'

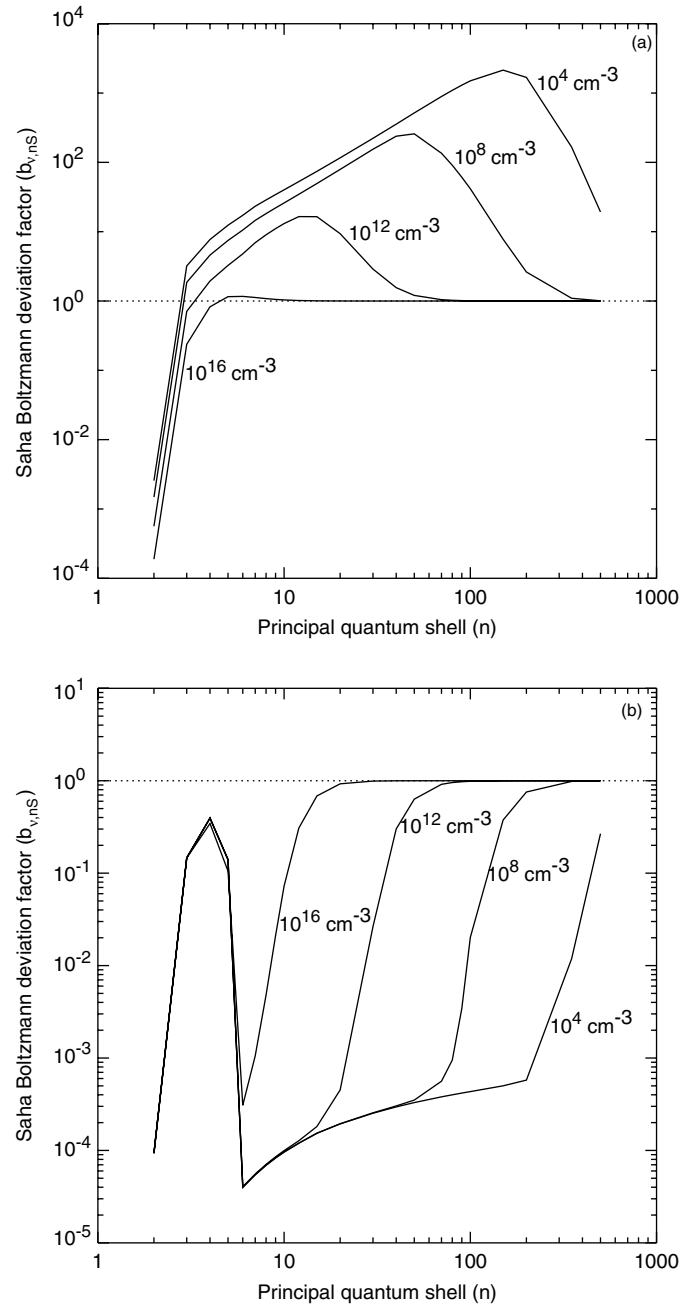

Figure 3. Bundle- nS population structure for O^{+4} recombining from and ionizing to O^{+5} at $T_e = 1.7 \times 10^5$ K. (a) $b_{(2s^2 \ ^1S) \ 2n}$ factors for doublet bundle- n populations built on the ground parent $2s^2 \ ^1S$ term. The enhanced b -factors at $n \sim 10$ –300 are due to dielectronic recombination. Curves show the progressive suppression of the high populations as the electron density increases. (b) $b_{(2s2p \ ^3P) \ 2n}$ factors for doublet bundle- n populations built on the metastable parent $2s2p \ ^3P$ term. The abrupt transition to underpopulations at $n \sim 4$ is due to secondary Auger transition (LS coupling allowed breakdown type) to the 1S parent system.

Table 2. Excited state structures and partial GCR ionization coefficients calculated for the Be–B series. Ionization coefficient nomenclature is $\text{SCD}_{\rho \rightarrow (v) (2S+1)n, v'}$ where ρ indexes the lowest metastable of the parent/spin system, with v the parent of the spin system, and v' indexes the final metastable state. ‘d’ denotes direct ionization and ‘e–a’ denotes inner shell excitation–autoionization contributions.

Final parent metastable	Intermediate system	Initial metast.	GCR ionization coefficient	Type
1	$(2s^2 \ ^1S) \ ^2n$	1	$\text{SCD}_{1 \rightarrow (1) \ ^2n, 1}$	d
1	$(2s2p \ ^3P) \ ^2n$	1	$\text{SCD}_{1 \rightarrow (2) \ ^2n, 1}$	e–a
2		1	$\text{SCD}_{1 \rightarrow (2) \ ^2n, 2}$	d
1	$(2s2p \ ^3P) \ ^4n$	2	$\text{SCD}_{2 \rightarrow (2) \ ^4n, 1}$	e–a (IC)
2		2	$\text{SCD}_{2 \rightarrow (2) \ ^4n, 2}$	d

before ρ is reached. This gives the new *parent cross coupling coefficient* $\text{XCD}_{v \rightarrow (v) (2S+1)n, v'}$. Note that in applications, it is the coefficients summed over intermediate states which are required:

$$\text{XCD}_{v \rightarrow v'} = \sum_{v, S} \text{XCD}_{v \rightarrow (v) (2S+1)n, v'}. \quad (37)$$

Behaviours are illustrated in figures 4(a) and (b).

2.2. The low-level + projection model

Consider now the set of low levels of an ion. For GCR studies, we are concerned with complete sets of low levels associated with the valence electron in the ground and excited n -shells. The span of the low levels is $\Delta n_{01} = n_1 - n_0$ with n_0 denoting the ground complex valence n -shell and n_1 the highest resolved n -shell. For light elements and spectroscopy which extends up to the visible range, we seek $\Delta n_{01} = 1$ at minimum and 2 preferably.

The solution for the populations and effective coefficients follows the theory of section 1.2.1 and is numerically straightforward, carried out in the population representation (called the p -representation), rather than b -factor or c -factor representations (see equation (34) and the following lines). The use of the c -factor representation, where $c = b - 1$, is essential for cancellation error avoidance in computation of the very high level population structure, but is not necessary for the low levels. The construction of the C_{ij} and $r_{i,v}$ coefficients is by spline interpolation in electron temperature of data extracted from archives. Expansion of indirect projection data and its amalgamation with the resolved direct data is by weight matrices:

$$\begin{aligned} C_{i,j} &= C_{ij}^{\text{dir}} + \sum_{v, S} \omega_{ij:v, S}^c C_{n, n':v, S}^{\text{indir}}, \\ r_{i,v} &= r_i^{\text{dir}} + \sum_S \omega_{i:v, S}^r r_{n:v, S}^{\text{indir}}, \\ L_i &= L_i^{\text{dir}} + \sum_{v, S} \omega_{i:v, S}^L L_{n:v, S}^{\text{indir}}, \end{aligned} \quad (38)$$

where $i \in n$ and $j \in n'$. Introducing the term statistical weight fractions

$$\omega_{i:n:v, S} = \frac{(2S_i + 1)(2L_i + 1)}{\sum_{j \in n} (2S_j + 1)(2L_j + 1)} \quad (39)$$

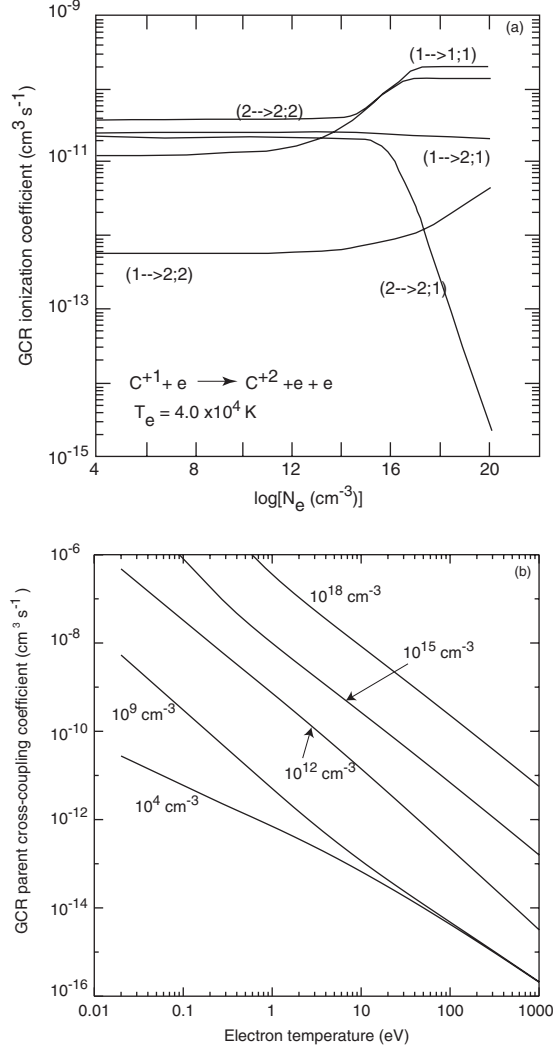

Figure 4. Bundle- nS generalized collisional-radiative coefficients. T_e is the electron temperature and N_e the electron density. (a) $C_{\rho}^{+1} + e \rightarrow C_{\nu}^{+2} + e + e$ for different initial metastable, ρ , final states, ν , and intermediate parent/spin systems. Curves are labelled as $SCD(\rho \rightarrow (\nu')^{2S+1}n; \nu)$ where $\rho = 1 \equiv (2s^2 2p^2 P)$, $\rho = 2 \equiv (2s 2p^2 {}^4P)$, $\nu, \nu' = 1 \equiv (2s^2 {}^1S)$ and $\nu, \nu' = 2 \equiv (2s 2p^3 P)$. (b) $O^{+3}[2s 2p^2 {}^4P] + e \rightarrow O^{+3}[2s 2p^2 {}^2P] + e$ parent cross-coupling coefficients. Both $O^{+2}[(2s 2p^2 {}^4P)^3 n]$ and $O^{+2}[(2s 2p^2 {}^4P)^5 n]$ recombined systems are included. The autoionization pathway for the former is allowed in LS-coupling, but for the latter proceeds only in intermediate-coupling (see section 2.3). Such coefficients follow broadly the behaviour of recombination coefficients.

then

$$\begin{aligned}
 \omega_{ij:v,S}^c &= \omega_{S_v,S} \omega_{i:n:v,S} & \text{for } n \neq n' \\
 \omega_{ij:v,S}^c &= \omega_{S_v,S} \\
 \omega_{i:v,S}^r &= \omega_{i:n:v,S} & \text{for } n = n' \\
 \omega_{i:v,S}^L &= \omega_{S_v,S}
 \end{aligned} \tag{40}$$

and $\omega_{S_v,S}$ is as defined in equation (33). Table 3 illustrates the C_{ij} weighting.

Table 3. Fractionizing of bundle- nS matrix projection onto low levels for B-like ions with two resolved n -shells.

Index	Term	Spin	Parent	Shell	n -shell weights	
					$n = 2$	$n = 3$
1	$2s^2 2p^2 \ ^2P$	2	1	2	0.25	—

10	$2s 2p 3s \ ^4P$	4	2	3	—	0.1089
11	$2s 2p 3p \ ^4D$	4	2	3	—	0.1881
12	$2s 2p 3p \ ^4S$	4	2	3	—	0.0297
13	$2s 2p 3p \ ^4P$	4	2	3	—	0.1089
14	$2s 2p 3d \ ^4F$	4	2	3	—	0.2673
15	$2s 2p 3d \ ^4D$	4	2	3	—	0.1881
16	$2s 2p 3d \ ^4P$	4	2	3	—	0.1089

In the deduction of spectral emission coefficients between low levels there can be some confusion. Following the definition of equation (21), in the resolved low level picture, the emission coefficient is referred to a particular metastable. If metastables are neglected, so that there is only a ground state and all other levels are viewed as excited, the reference is to the ground state. On the other hand, a metastable treated as an ordinary excited level will have a quasistatic population comparable to that of the ground so that $\sum_i N_i = N_{\text{tot}} \neq N_1$ and $\text{PEC}_{\text{tot}, j \rightarrow k} = \text{PEC}_{1, j \rightarrow k} N_1 / N_{\text{tot}}$, and this is the coefficient which should be used with a ‘stage-to-stage’ (that is un-generalized picture) ionization balance. Figure 5 illustrates the behaviour of low level populations. The graph is of the parameter $\mathcal{F}_{i1}^{(\text{exc})}$ from equation (20).

2.3. Specific reactions

Energy levels for high bundle- nS levels and their A -values, Maxwell averaged collision strengths, radiative recombination coefficients, dielectronic recombination coefficients and ionization coefficients are generated from a range of parametric formulae and approximations described in earlier works (Burgess and Summers 1976, Summers 1977, Summers and Hooper 1983, Burgess and Summers 1987, Summers 2004). High quality specific data when available are accessed from archives and substituted for the default values. This is a systematic procedure for dielectronic coefficients (see sections 2.3.1 and 5 below).

Figure 5. Low level population structure of Ne^{+7} . The excitation part driven by the $1s^2 2s^2 S$ ground state is denoted by N_1 . Terms are labelled as 2: $2p^2 P$, 3: $3s^2 S$, 4: $3p^2 P$, 5: $3d^2 D$, 6: $4s^2 S$, 7: $4p^2 P$, 8: $4d^2 D$. At low density, the population ratios $N_i/N_e N_1$ become flat tending to the coronal values. At high density the population ratios decrease inversely with the electron density, N_e , tending to the Saha-Boltzmann values. The intermediate region is the collisional-radiative regime.

For low levels, a complete basis of intermediate coupling energy level, A -value and scaled Born approximation collision data, spanning the principal quantum shell range $n_0 \leq n \leq n_1$ is generated automatically using Cowan (1981) or Autostructure (Badnell, 1986) procedures. This is called our *baseline* calculation. These data are merged with more restricted (in level coverage) but similarly organized highest quality data from archives where available (e.g. R -matrix data such as Ramsbottom *et al* (1995)). The data collection is compressed by appropriate summing and averaging to form a complete LS term basis and augmented with comprehensive high quality LS resolved dielectronic recombination, radiative recombination and collisional ionization coefficients mapped from archives (see sections 2.3.1, 2.3.2 and 5 below). The radiative data have their origin in the work of Burgess and Summers (1987). The final data collection is called a *specific ion file* (ADAS data format *adf04*). The detailed content is examined in section 3. Details of state selective dielectronic recombination and ionization coefficients are given in the following subsections.

2.3.1. State-selective dielectronic recombination. State selective dielectronic recombination coefficients are required to all resolved low levels and to all bundle- nS shells for the various initial and intermediate state metastable parents ν for GCR modelling. These are very extensive data and have been prepared for the present GCR work through an associated international ‘DR Project’ summarized in Badnell *et al* (2003) (hereafter called *DR - paper I*) and detailed in subsequent papers of the series. Based on the independent particle, isolated resonance, distorted wave (IPIRDW) approximation, the partial dielectronic recombination rate coefficient

$\alpha_{v \rightarrow i}^{(d)}$ from an initial metastable state v into a resolved final state i of an ion \mathcal{A}^{+z} is given by

$$\alpha_{v \rightarrow i}^{(d)} = \left(\frac{4\pi a_0^2 I_H}{kT_e} \right)^{3/2} \sum_{p,j} \frac{\omega_{p,j}}{2\omega_v} e^{-E_c/kT_e} \times \frac{\sum_l A_{p,j \rightarrow v, E_{cl}}^a A_{p,j \rightarrow i}^r}{\sum_h A_{p,j \rightarrow h}^r + \sum_{m,l} A_{p,j \rightarrow m, E_{cl}}^a}, \quad (41)$$

where $\omega_{p,j}$ is the statistical weight of the $(N+1)$ -electron doubly-excited resonance state j , ω_v is the statistical weight of the N -electron target state and the autoionization (A^a) and radiative (A^r) rates are in inverse seconds. The suffix p is used here to denote a parent ion state. E_c is the energy of the continuum electron (with angular momentum l), which is fixed by the position of the resonances. Note that the parent states p are excited, that is, they exclude the metastable parents v' . The code AUTOSTRUCTURE (Badnell 1986, Badnell and Pindzola 1989, Badnell 1997) was used to calculate multi-configuration LS and intermediate coupling energy levels and rates within the IPIRDW approximation. The code makes use of both non-relativistic and semi-relativistic wavefunctions (Pindzola and Badnell 1990) and is efficient and accurate for both the resolved low level and high- n shell problems. Lookup tables (see section 5, *adf09*) are prepared comprising state selective recombination coefficients at a standard set of z -scaled temperatures, for each metastable parent, to all LS resolved terms of the recombined ion with valence electron up to n -shell $n_1^{(d)} \geq n_1$ (normally $n_1^{(d)} = 5$) and to bundle- nS levels of a representative set of n -shells (usually spanning n_0 to 999). These bundle- nS coefficients are simple sums over orbital states $l \in n$ and so apply at zero density. This provides an extensive, but still economical, tabulation.

In *DR paper-I*, we introduced an associated code, the ‘Burgess–Bethe general program’ BBGP. BBGP is used here as a support function in a model for the l -redistribution of doubly-excited states which provide a correction to the accurate, but unredistributed, dielectronic data. The redistributed data (regenerated in the same *adf09* format) are normalized to IPIRDW at zero density. The procedure is similar to that for singly excited systems. For LS-averaged levels, the number densities expressed in terms of their deviations, $b_{p,nl}$ from Saha–Boltzmann, and referred to the initial parent v' , are given by

$$N_{p,nl} = N_e N_{v'}^+ 8 \left[\frac{\pi a_0^2 I_H}{kT_e} \right]^{3/2} \frac{\omega_{p,nl}}{\omega_{v'}} e^{-E/kT_e} b_{p,nl}. \quad (42)$$

Thus, in the BBGP zero-density limit, with only a resonant capture from the v parent balanced by Auger breakup and radiative stabilization back to the same parent, we have

$$b_{p,nl} = \left(\frac{\sum_{l'} A_{p,nl \rightarrow v'k'l'}^a}{\sum_{l'} A_{p,nl \rightarrow v'k'l'}^a + A_{p,nl \rightarrow v',nl}^r} \right). \quad (43)$$

In the extended BBGP model, we include resonant capture from initial metastables other than the ground, dipole-allowed collisional redistribution between adjacent doubly-excited l -substates of the same n by secondary ion- and electron-impact and losses by ‘alternate’ Auger break-up and parent radiative transition pathways. The population equations for the l -substates of a doubly-excited n -shell become

$$\begin{aligned} & - (N_e q_{nl-1 \rightarrow nl}^{(e)} + N_{z_{\text{eff}}} q_{nl-1 \rightarrow nl}^{(z_{\text{eff}})}) N_{p,nl-1} \\ & + \left(\sum_{l'=l \pm 1} N_e q_{nl \rightarrow nl'}^{(e)} + \sum_{l'=l \pm 1} N_{z_{\text{eff}}} q_{nl \rightarrow nl'}^{(z_{\text{eff}})} + \sum_{p_1=1}^{p-1} \sum_{l'=l-1}^{l+1} A_{p,nl \rightarrow p_1, \kappa l'}^a + \sum_{p_1=1}^{p-1} A_{p,nl \rightarrow p_1, nl}^r \right) N_{p,nl} \\ & - (N_e q_{nl+1 \rightarrow nl}^{(e)} + N_{z_{\text{eff}}} q_{nl+1 \rightarrow nl}^{(z_{\text{eff}})}) N_{p,nl+1} \\ & = N_e \sum_{v=1}^M \sum_{l'=l-1}^{l+1} q_{v, \kappa l' \rightarrow p, nl}^c N_v + \sum_{p_1=p+1}^P A_{p_1, nl \rightarrow p, nl}^r N_{p_1, nl}. \end{aligned} \quad (44)$$

Figure 6. O^{4+} dielectronic recombination. $b_{p,nl}$ factors as a function of outer electron orbital angular momentum, l , for doubly-excited states of O^{3+} relative to $O^{4+} 2s^2 \ ^1S$ for $p = 2s2p \ ^1P$ and $2s3p \ ^1P$, $n = 20$, $T_e = 10^6$ K, $N_e = N_p$, $Z_{\text{eff}} = 1$. Cases: 1. $N_e = 10^{10} \text{ cm}^{-3}$; 2. $N_e = 10^{12} \text{ cm}^{-3}$; 3. $N_e = 10^{13} \text{ cm}^{-3}$; 4. $N_e = 10^{14} \text{ cm}^{-3}$; 5. $N_e = 10^{15} \text{ cm}^{-3}$. Note the alternative Auger channel reduction for the $p = 2s3p \ ^1P$ graphs.

q^c denotes resonance capture coefficients, M denotes the number of parent metastables which are the starting point for resonance capture whereas P denotes the number of true excited parent states. Ion impact redistributive collisions are effective and are represented in the equations as z_{eff} ion contributions. The density corrected bundle- nS recombination coefficients are then

$$\alpha_{v' \rightarrow v', nS}^{(d, \text{IPIRDW})}(N_e) = \alpha_{v' \rightarrow v', nS}^{(d, \text{IPIRDW})}(N_e = 0) \frac{\sum_l \alpha_{v' \rightarrow v', nl}^{(d, \text{BBGP})}(N_e)}{\sum_l \alpha_{v' \rightarrow v', nl}^{(d, \text{BBGP})}(N_e = 0)}. \quad (45)$$

Details are given in *DR paper-I*. Figure 6 shows the effects of redistribution of the doubly excited $b_{p,nl}$ factors in the recombination of O^{4+} .

Autoionization rate calculations in LS coupling exclude breakup of non-ground metastable parent based ‘singly excited’ systems by spin change. Such breakup occurs only in intermediate coupling but cannot be ignored for a correct population assessment even in light element ions. These rates are computed in separate intermediate coupling dielectronic calculations. These rates are main contributors to the parent metastable cross-coupling identified earlier (cf the $O^{+2}[(2s2p^2 \ ^4P) \ ^5n]$ intermediate states in figure 4(b) leading back to the $O^{+3}(2s^2 2p \ ^2P)$ parent).

2.3.2. State-selective ionization. Direct ionization coefficients for excited n -shells in bundle- nS population modelling are evaluated in the exchange-classical-impact parameter (ECIP) approximation (Burgess and Summers 1976). The method which merges a symmetrized classical binary encounter model with an impact parameter model for distant encounters is relatively simple and of moderate precision, but has a demonstrated consistency and reliability for excited n -shells in comparison with more elaborate methods. There is a higher precision requirement for state selective ionization from metastable and low levels. Such an ionization includes direct and excitation/autoionization parts, but the latter only through true excited parents. Stepwise ionization is handled in the collisional–radiative population models.

There are extensive ionization cross-section measurements, but these are in general unresolved and so are of value principally for renormalizing of resolved theoretical methods. The most powerful theoretical methods used for excitation, namely *R*-matrix with pseudostates (RMPS) (Bartschat and Bray 1996, Ballance *et al* 2003) and convergent-close-coupling (CCC) (Bray and Stelbovics 1993), have some capability for ionization, but at this stage are limited to very few electron systems as is the time-dependent-close-coupling (TDCC) (Pindzola and Robicheaux 1996, Colgan *et al* 2003) ionization method. For GCR calculations, we have relied on the procedures of Summers and Hooper (1983) for initial and final state resolution of total ionization rate coefficients and on the distorted wave approximation. The distorted wave method is our main method for extended GCR studies for many elements and most stages of ionization. RMPS and TDCC studies are directed mostly at the neutral and near neutral systems where the distorted wave method is least reliable (Loch *et al* 2005). We use the configuration average distorted wave (CADW) approach of Pindzola *et al* (1986). It has reasonable economy of computation while allowing access to complex, multi-electron ions, highly excited states, excitation/autoionization and radiation damping. It expresses the configuration averaged excitation cross-section for

$$(n_1 l_1)^{q_1+1} (n_2 l_2)^{q_2-1} \bar{k}_i l_i \rightarrow (n_1 l_1)^{q_1} (n_2 l_2)^{q_2} \bar{k}_f l_f \quad (46)$$

as

$$\bar{\sigma}_{\text{excit}} = \frac{8\pi}{\bar{k}_i^3 \bar{k}_f} (q_1 + 1) (4l_2 + 3 - q_2) \sum_{l_i, l_f} (2l_i + 1) (2l_f + 1) M_{2f;1i} \quad (47)$$

and the configuration averaged ionization cross-section for

$$(n_1 l_1)^{q_1+1} \bar{k}_i l_i \rightarrow (n_1 l_1)^{q_1} \bar{k}_e l_e \bar{k}_f l_f \quad (48)$$

as

$$\bar{\sigma}_{\text{ionis}} = \frac{32\pi}{\bar{k}_i^3 \bar{k}_e \bar{k}_f} (q_1 + 1) \sum_{l_i, l_e, l_f} (2l_i + 1) (2l_e + 1) (2l_f + 1) M_{ef;1i}, \quad (49)$$

where $M_{2f;1i}$ are squared two-body Coulomb matrix elements, $\bar{\sigma}$ denotes the average cross-section and \bar{k}_i , \bar{k}_f and \bar{k}_e denote average initial, final and ejected electron momenta, respectively, in the configuration average picture. The configuration average direct ionization cross-sections and rate coefficients may be unbundled back to the resolved form using angular factors obtained by Sampson and Zhang (1988). Note that the excitations described here are to auto-ionizing levels, and so resolved Auger yields may be used which are the same as those in the dielectronic calculations of section 2.3.1 above. In fact the ionization coefficient calculation results are structured and archived in ADAS (format *adf23*) in a manner very similar to the state selective dielectronic recombination. Extensive studies have been carried out on light and heavy elements (Colgan *et al* 2003, Loch *et al* 2003).

3. Fundamental atomic data for low levels of ions

For bundle-*nS* modelling, the expected fundamental data precision is $\lesssim 30\%$ for excitation and ionizing collisional rate coefficients, $\lesssim 10\%$ for *A*-values and state selective recombination coefficients and $\lesssim 1\%$ for energies.

For low level modelling many sources are used. A rating is given for the classes of fundamental data for the ions of carbon, oxygen and neon in table 4 which is based on the following considerations. For energy levels, categories are *a* spectroscopic, *b* $\lesssim 0.5\%$ and *c* $\lesssim 1.0\%$. Category *c* is anticipated from *ab initio* multi-configuration structure

Table 4. Fundamental data precision categorizing for the ions of carbon, oxygen and neon. The definition of the categories and justification of the categories for Ne⁺⁶ are given in the text.

Ion	E	A	Υ_{ij}		$\alpha^{(r)}$	$\alpha^{(d)}$	S
			$\Delta n = 0$	$\Delta n > 0$			
C ⁰	a	b	b	b,c	b	b	b
C ⁺¹	a	b	b	b,c	b	b	b
C ⁺²	a	b	a,b	b,c	b	b	b
C ⁺³	a	a,b	b	b,c	b	b	b
C ⁺⁴	a	a	b	b,c	b	b	b
C ⁺⁵	a	a	b	b	b	b	b
O ⁰	a	b,c	b	b	b	b	b
O ⁺¹	a	b,c	b	b	b	b	b
O ⁺²	a	b,c	a,b	b	b	b	b
O ⁺³	a	b	a	a	b	b	b
O ⁺⁴	a	b	a	a	b	b	b
O ⁺⁵	a	b	b	b	b	b	b
O ⁺⁶	a	a	b	b,c	b	b	b
O ⁺⁷	a	a	b	b,c	b	b	b
Ne ⁰	a	b,c	b	c	b	b	b
Ne ⁺¹	a	c	b	b	b	b	b
Ne ⁺²	a	b	a	b	b	b	b
Ne ⁺³	a	b	a	b	b	b	b
Ne ⁺⁴	a	b	a	b	b	b	b
Ne ⁺⁵	a	b	a	b	b	b	b
Ne ⁺⁶	a	b	a	b	b	b	b

Ne ⁺⁸	a	a	b	c	b	b	b
Ne ⁺⁹	a	a	b	c	b	b	b

calculations, *b* from such calculations with extended optimizing and *a* reflects direct inclusion of experimental energies from reference sources. For A-values, categories are *a* \lesssim 5%, *b* \lesssim 10% and *c* \lesssim 25%. Category *c* is anticipated from our baseline calculations, *b* from optimized multi-configuration structure calculations with extended optimizing and *a* from specific studies in the literature. For electron impact Maxwell averaged collision strengths, Υ , the categories are *a* \lesssim 10%, *b* \lesssim 20% and *c* \lesssim 35%. Category *c* is from our baseline calculations, *b* from distorted wave calculations and *a* from specific *R*-matrix calculations, equivalent methods or experiment. For radiative recombination, the categories are *a* \lesssim 5%, *b* \lesssim 10% and *c* \lesssim 50%. Category *c* is from scaled methods using hydrogenic matrix elements, *b* from distorted wave one-electron wave functions in an optimized potential using spectroscopic energies and *a* from specific *R*-matrix calculations and experiment. Category *b* is the baseline in ADAS. For dielectronic recombination, the categories are *a* \lesssim 20%, *b* \lesssim 30% and *c* \lesssim 45%. Category *c* is from BBGP approximations, *b* from LS-coupled calculations using Autostructure from the DR Project and *a* from IC-coupled calculations using Autostructure with parent and lowest resonance energy level adjustments from the DR Project. Category *b* is the baseline in ADAS. It is to be noted that the theoretical relative precision which is consistent with the variation between the three categories is 15% better, but dielectronic recombination comparisons with experiment still show unexplained discrepancies at the 20% level, so the present categories are safe. For ionization, the categories are *a* \lesssim 10%, *b* \lesssim 25% and *c* \lesssim 40%. Category *c* is from ECIP approximations, *b* from configuration average with angular factor term

resolution and a from RMPS, TDCC calculations and experiment. Category b is the baseline in ADAS.

As indicated in section 2.3, these various data are assembled in an *adf04* file which is sufficient to support the primary low-level population calculation. The tabulations are at a set of temperatures arising from a fixed set of z -scaled temperatures (see section 2.1.1) which spans the full range to asymptotic regions of reaction data. Collision data are converted to these ranges using *C-plots* (Burgess and Tully (1992) and this procedure also flags data errors or queries. The precision of the specific ion file determines the achievable precision of all derived populations, emissivities and collisional–radiative coefficients (Whiteford *et al* 2005, O’Mullane *et al* 2005). The assembling of data in the *adf04* is systematic and orderly. A comment section at the end of the file details the assembly steps, implementer, codes used and dates. This includes baseline and supplementation files, merging, LS compression, dielectronic recombination data inclusion etc. Also there is extended detail of original data sources and a history of updates. A given *adf04* file represents a ‘snapshot’ of the state of available knowledge at the time. It is subject to periodic review and ADAS codes (see section 5) are designed to enable easy reprocessing of all derived data following fundamental data update. The grading for each ion given in table 4 is justified and supported by the comments from its *adf04* file. A summary from Ne⁺⁶ is given in the following paragraphs in illustration. For Ne⁺⁶, the low levels span 44 terms, including up to the $n = 5$ shell built on the parent $1s^2 2s^1 S$ and $n = 3$ shell built on the $1s^2 2p^1 S$. Only the $1s^2 2s^1 S$ parent is treated as a metastable from the GCR point of view. The intermediate coupled baseline dataset is *copmm#10-ic#ne6.dat* with preferred supplementary energy A -value and Υ data merged from *copjl#be-ic#ne6.dat*. Ionization potentials and energy levels are from the NIST standard reference database apart from $2p3p^1 S$ (Kelly 1987) and $2p3d^3 F$ levels by Ramsbottom *et al* (1995). The categorization is a . A -values were drawn from the Opacity Project (Opacity Project Team 1995, Tully *et al* 1991) as justified (for N IV and O V) by Wiese *et al* (1996) and supported/adjusted by $\lesssim 3\%$ by Fleming *et al* (1996a and 1996b), Jönsson *et al* (1998), Froese Fischer *et al* (1997a, 1997b), Nussbaumer and Storey (1979), Sampson *et al* (1984) and Ramsbottom *et al* (1995). Category b is safe. Υ s are taken from Ramsbottom *et al* (1995). These are for a 26 LS eigenstate multichannel R -matrix calculation. The categories assigned are a and b . Radiative and dielectronic recombination and ionization all follow the baselines in ADAS, that is, categories b , although the summed and averaged ionization rate coefficient (over metastables) is normalized to experiment.

4. Illustrative results

Figure 7 shows PEC coefficients for the C II 858 Å spectrum line. The coefficients depend on both electron temperature and electron density in general. A common practice in spectral analysis is to observe principally the strongest resonance line of an ion. Such an emission is driven largely from the ground state (figure 7(a)) and because of the large A -value, the density sensitivity occurs at relatively high density. Thus such a resonance line emission at moderate to low densities mostly reflects temperature and the distribution of the ionization stages. Comparison in near equilibrium ionization balance plasmas of line ratios from the same ion, by contrast, is mostly directed at electron density and relies on the presence of metastables and spin changing collisional processes to confer the sensitivity. As shown earlier, the balance of the dominant ground and metastable populations is disturbed in dynamic plasmas, and so density sensitivity may be modified by the dynamic state. The distinction of the metastable driven PEC in GCR modelling, as illustrated in figure 7(b), allows a more complete diagnostic study and the possibility of separation of the two effects. In strongly recombining plasmas (most commonly photo-ionized astrophysical plasmas) the direct contribution of recombination

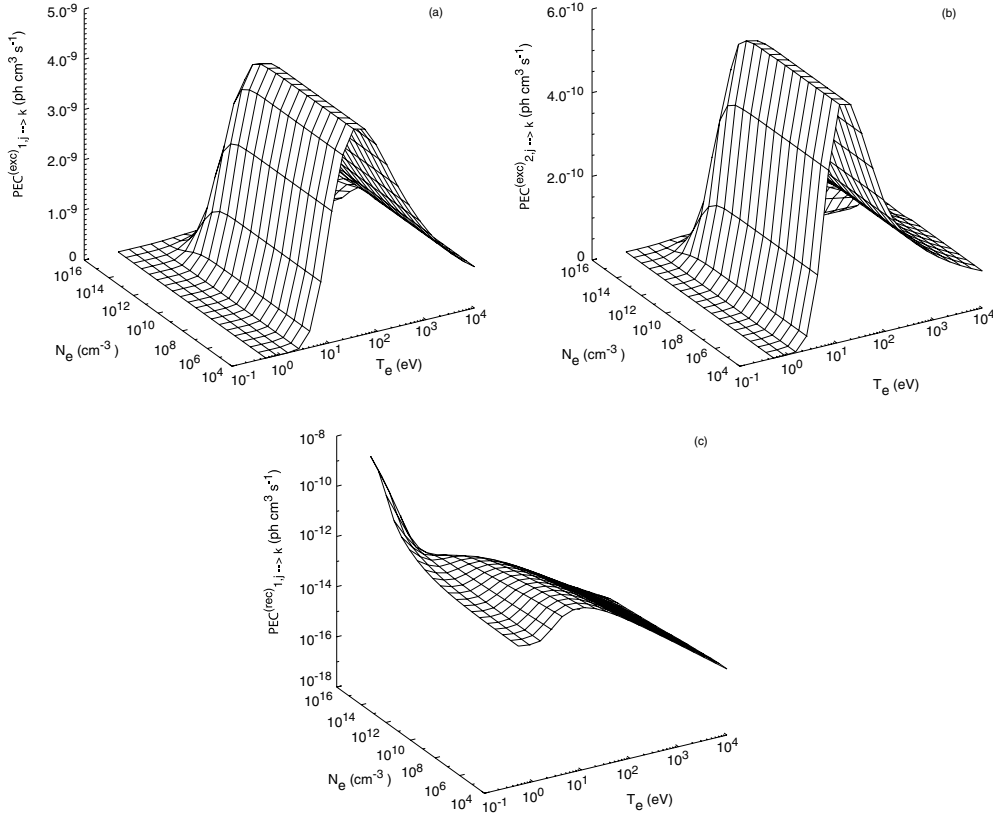

Figure 7. Excitation and recombination photon emissivity functions, PECs, driven by the ground metastables, are shown for the C II 858 Å spectrum line. The coefficients depend on both the electron temperature and the electron density. The (exc) part decreases at high electron density principally due to stepwise ionization losses from the upper level of the transition. The behaviour of the (rec) part shows both the suppression of dielectronic recombination at moderate density and then the enhancement due to three-body recombination at high density and low temperature.

to the emission may dominate the excitation part. The $\text{PEC}^{(\text{rec})}$, as illustrated in figure 7(c), is then required. In the fusion context, multi-chordal spectral observations are important for the study of impurity transport especially near sources. Visible and quartz UV observations are convenient and this places a requirement for PECs from higher quantum shells. It is this, primarily, which defines the span of our *low-levels* for population modelling. Emission from higher n -shells is significantly affected by cascading from yet higher levels. The full machinery of projection as described in section 2.1 is necessary for our global ambition of 20% precision for emissivity coefficients.

Figure 8 illustrates the GCR recombination coefficients. At low electron density, radiative and dielectronic recombination dominate. For capture from metastables, alternate Auger branching can largely suppress the dielectronic part of the surfaces. Thus figure 8(a) shows the characteristic exponential rise at the temperature for excitation of the main parent (core) transition of dielectronic recombination and then the subsequent fall-off (as $\sim T_e^{-3/2}$), in contrast with 8(c). At moderate densities, suppression of the high n -shell populations, principally populated by dielectronic recombination, through re-ionization occurs and the

Figure 8. Generalized collisional–radiative recombination coefficients for $O^{+4} + e \rightarrow O^{+3}$ (a) $ACD(2s^2\ ^1S \rightarrow 2s^22p\ ^2P)$ (b) $ACD(2s^2\ ^1S \rightarrow 2s2p^2\ ^4P)$ (c) $ACD(2s2p\ ^3P \rightarrow 2s2p^2\ ^4P)$.

coefficient falls in the dielectronic recombination region. At a very high density, three-body recombination becomes effective, preferentially beginning at the lower electron temperatures. It is evident that recombination is less effective from the metastable at relevant ionization balance temperatures. Models which ignore the role of capture from the metastable parent (which may be the dominant population) can lead to substantial errors in recombination coefficients, while simply excluding all capture from the metastable cannot deliver the precision sought for current modelling. For light elements in astrophysical plasmas, the zero-density coronal assumption for the recombination coefficient is still frequently made. This cannot be justified even at solar coronal densities.

Figure 9 illustrates the GCR ionization coefficients. At low electron density, the coefficient is dominated by direct ionization, including excitation/auto-ionization, from the driving metastable. Relatively high electron densities are required before the stepwise contribution begins. It is primarily the excitation to, and then further excitation and ionization from, the first excited levels which controls this. The ground and metastable resolved coefficients both show the same broad behaviour as the usual (stage to stage) collisional–radiative coefficient, tending to a finite limit at very high density. It is to be noted that the XCD coefficients are required to be able to construct a meaningful stage-to-stage collisional–radiative ionization coefficient from the generalized progenitors. It remains the case that most plasma modelling (certainly in the fusion area) is not adjusted to the use of the generalized coefficients as source

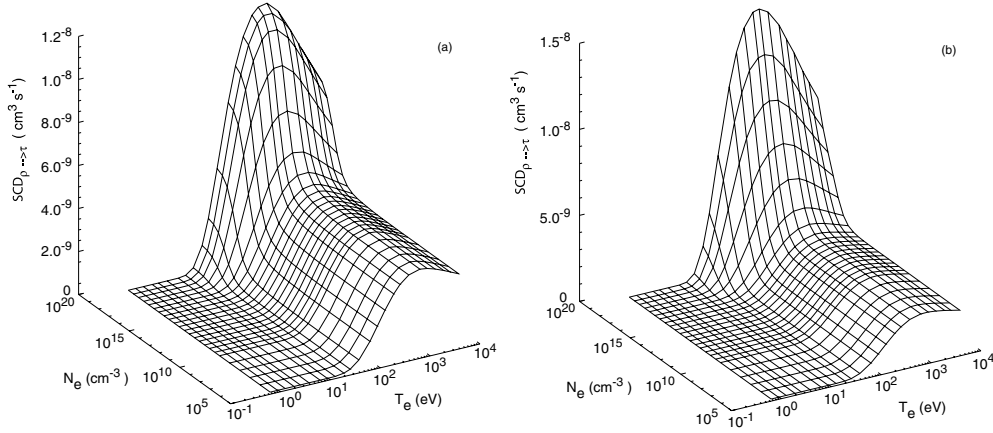

Figure 9. Generalized collisional-radiative ionization coefficients for $O^{+3} + e \rightarrow O^{+4} + e + e$ (a) $SCD(2s^2 2p^2 P \rightarrow 2s^2 ^1 S)$ (b) $SCD(2s^2 2p^2 P \rightarrow 2s 2p^3 P)$.

terms. Reconstruction of stage to stage source terms (at the price of a reduction in modelling accuracy) from the generalized coefficients is still a requirement and is addressed more in detail in section 5.

The generalized coefficients may be used to establish the equilibrium ionization balance for an element in which the dominant ground and metastable populations are distinguished, that is the fractional abundances

$$\left(\frac{N_{\sigma}^{[z]}}{N^{[tot]}} \right) : \sigma = 1, \dots, M_z; z = 0, \dots, z_0, \quad (50)$$

where M_z is the number of metastables for ionization stage z and

$$N^{[tot]} = \sum_{z=0}^{z_0} N^{[z]} = \sum_{z=0}^{z_0} \sum_{\sigma=0}^{M_z} N_{\sigma}^{[z]} \quad (51)$$

in equilibrium. Writing $N^{[z]}$ for the vector of populations $N_{\sigma}^{[z]}$, the equilibrium population fractions are obtained from a solution of the matrix equations.

$$\begin{bmatrix} \mathcal{C}^{[0,0]} & N_e \mathcal{R}^{[1 \rightarrow 0]} & 0 & \vdots \\ N_e \mathcal{S}^{[0 \rightarrow 1]} & \mathcal{C}^{[1,1]} & N_e \mathcal{R}^{[2 \rightarrow 1]} & \vdots \\ 0 & N_e \mathcal{S}^{[1 \rightarrow 2]} & \mathcal{C}^{[2,2]} & \vdots \\ 0 & 0 & N_e \mathcal{S}^{[2 \rightarrow 3]} & \vdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix} \begin{bmatrix} N^{[0]} \\ N^{[1]} \\ N^{[2]} \\ N^{[3]} \\ \vdots \end{bmatrix}_{\text{equil}} = 0. \quad (52)$$

These in turn may be combined with the PLT and PRB to obtain the equilibrium radiated power loss function for the element as

$$P^{[tot]} = \sum_{z=0}^{z_0} P^{[z]} \left(\frac{N^{[z]}}{N^{[tot]}} \right)_{\text{equil}} = \sum_{z=0}^{z_0} \sum_{\sigma=0}^{M_z} (\text{PLT}_{\sigma}^{[z]} + \text{PRB}_{\sigma}^{[z]}) \left(\frac{N_{\sigma}^{[z]}}{N^{[tot]}} \right)_{\text{equil}}. \quad (53)$$

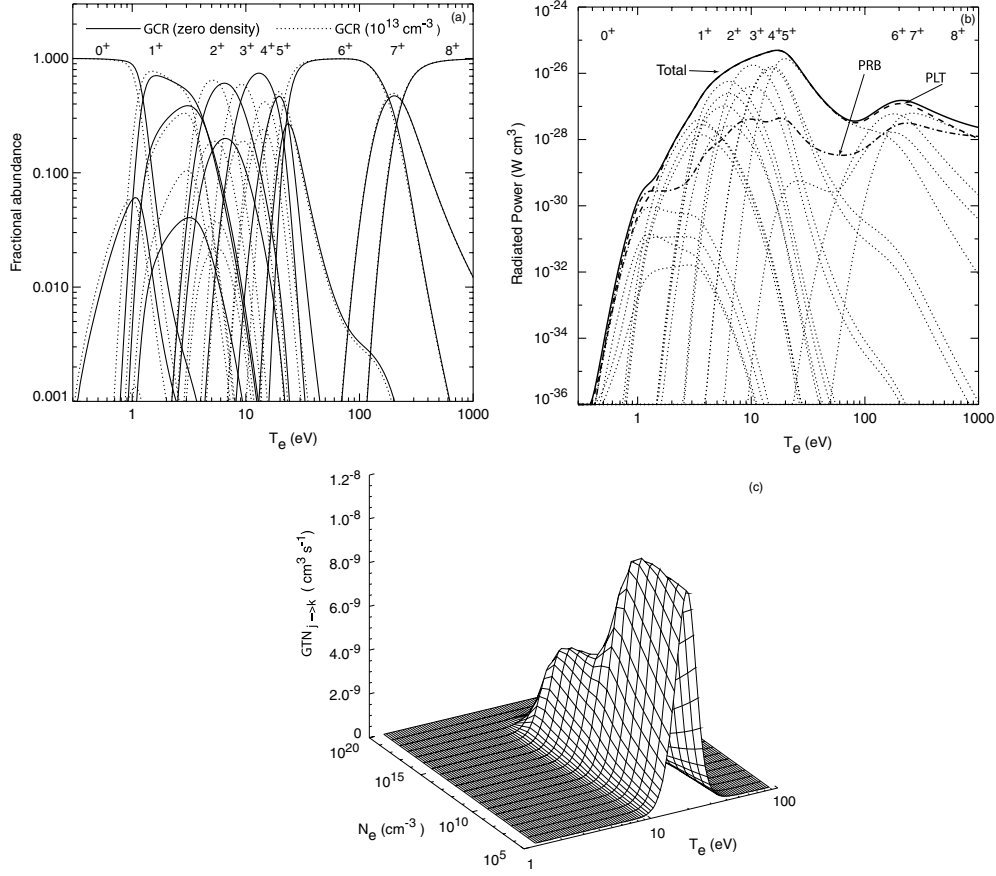

Figure 10. Equilibrium ionization balance of oxygen. (a) Equilibrium fractional abundances of metastables from the generalized collisional–radiative (b) The total radiated power function showing the components driven by the different metastables (c) The GTN function for the O II 629.7 Å line showing the contributions parts from the different metastables of the z -times and $(z + 1)$ -times ionized ions.

The equilibrium fractional abundances and equilibrium radiated power function are illustrated in figure 10. It is useful at this point to draw attention to emission functions which combine emission coefficients with equilibrium fractional abundances. They are commonly used in differential emission measure analysis of the solar atmosphere (Lanzafame *et al* 2002) where they are called $G(T_e)$ functions. In solar astrophysics, it is assumed that the $G(T_e)$ are functions of the single parameter T_e (either from a zero-density coronal approximation or by specification at fixed density or pressure) and usually the abundance of hydrogen relative to electrons N_H/N_e is incorporated in the definition. For finite density plasmas, in the generalized collisional–radiative picture, we define GTN functions, parametrized by T_e and N_e as

$$\text{GTN}_{j \rightarrow k}^{[z]} = \sum_{\sigma} \text{PEC}_{\sigma, j \rightarrow k}^{[z](\text{exc})} \left(\frac{N_{\sigma}^{[z]}}{N_{[\text{tot}]}} \right)_{\text{equil}} + \sum_{\nu'} \text{PEC}_{\nu', j \rightarrow k}^{[z](\text{rec})} \left(\frac{N_{\nu'}^{[z+1]}}{N_{[\text{tot}]}} \right)_{\text{equil}}. \quad (54)$$

These are strongly peaked functions in T_e . The precision of the present modelling and data, including the full density dependence, is in principle sufficient to allow bivariate differential

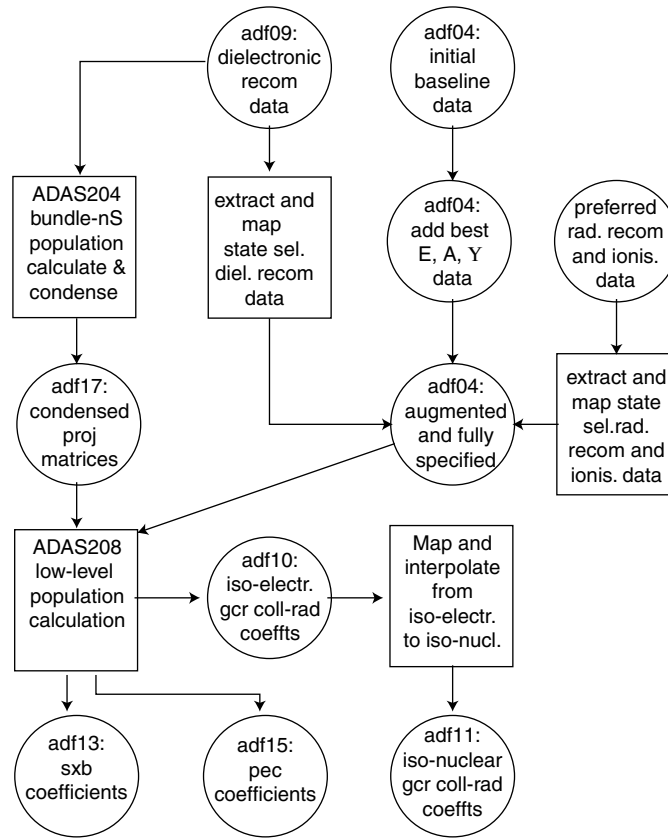

Figure 11. Schematic of computational steps in the production of generalized collisional–radiative data. Data sets are shown by circles and program elements by rectangles. The key members have been incorporated and assigned names in the ADAS system.

emission measure analysis (Judge *et al* 1997) although this remains to be carried out. The general behaviour of a GTN function is illustrated in figure 10(c).

5. Computations and archiving derived data for applications

The organization of the main calculations and data flow is shown in figure 11. The calculations executed for the paper have been implemented in general purpose codes and attention has been given to the precise specification of all data sets and the machinery for accessing and manipulating them. This includes initial data, intermediate and driver data as well as the final GCR products and follows ADAS Project practice. Population structure modelling requires an initial input dataset of energy levels, transition probabilities and collisional rates of ADAS data format *adf04* which is complete for an appropriate designated set of low levels. For the light elements, best available data were assembled and verified as described in section 3. These data are substitutes for more moderate quality, but complete, *baseline* data prepared automatically (see *GCR-paper III*). The *adf04* files are required for LS-terms. In practice, we find it most suitable to prepare the data for LSJ levels and then bundle back to terms. For GCR modelling, state selective recombination and ionization coefficients must be added to form

the fully specified *adf04* file. The LS-coupled dielectronic coefficients are mapped in from very large comprehensive tabulations of data format *adf09* prepared as part of the *DR Project* (Badnell *et al* 2003). The resulting *adf04* files are the ADAS preferred data sets and are available for elements helium to neon.

The two population codes, called ADAS204 and ADAS208, work together. ADAS204 is the bundle- nS model. Data on the metastable parent structure, quantum defects, auto-ionization thresholds and autoionisation rates are required. These data may be extracted from the *adf04* files, and it has been helpful to make the driver dataset preparation automatic. High quality shell selective dielectronic data are essential, and this is part of the provision in the *adf09* files described in the previous paragraph. ADAS204 provides complete population solutions, but extracts from these solutions the condensed influence on the low n -shells, as *projection matrices*, for connection with the calculations of ADAS208. It is to be noted that the main on-going development is the refinement of atomic collision rates between the key low levels. The projection matrices are not subject to frequent change and so are suitable for long-term archiving (*adf17*). ADAS208 is the low-level resolved population model which delivers the final data for application. It draws its key data from the fully configured *adf04* file and supplements these with projection data. The evaluation of the population structure takes place at an extended set of z -scaled electron temperatures and densities (see section 2), and this means that the resulting GCR coefficient data are suited to interpolation along iso-electronic sequences. Thus the initial tabulation of GCR coefficients is in iso-electronic datasets. It is convenient to implement the gathering and mapping from iso-electronic to iso-nuclear in a separate step, which also supports the merging back to the unresolved stage-to-stage picture if required. The production of PEC and SXB coefficients is directly to iso-nuclear oriented collections. The number of PECs from the population calculations can, in principle, be very large. We restrict these by a threshold magnitude and to particular important spectral regions. It is straightforward to rerun ADAS208 to generate PEC or SXB coefficients alone in spectral intervals of one's choice. The separation of the ADAS204 and ADAS208 tasks and the ease of modifying data within an *adf04* file means that 'what-if' studies on the sensitivity of the derived data to fundamental data uncertainty can readily be carried out. Special ADAS codes enable a detailed study of cumulative error and dominating sources of uncertainty such that error surfaces, for example for a PEC as a function of electron temperature and density, may be generated. Such error (uncertainty) analysis for theoretical derived coefficients and its utilization in the confrontation with diagnostic experiments is the subject of a separate work (see O'Mullane *et al* (2005)).

6. Conclusions

The requirements for precise modelling of spectral emission and the relating of ionization stages in thermal plasmas have been considered. Collisional–radiative methodologies have been developed and extended to enable the full role of metastables to be realized, so that this generalized (GCR) picture applies to most dynamically evolving plasmas occurring in magnetic confinement fusion and astrophysics.

The procedures are valid up to high densities. The studies presented in the paper explore the density effects in detail within the GCR picture and show that the density dependences of excited ion populations and of effective rate coefficients cannot be ignored.

Specific results are presented for light elements up to neon, and the computations are carried out in an atomic basis of terms (LS-coupled). Such modelling will remain sufficient up to about the element argon, beyond which a level basis (intermediate coupling) becomes necessary. Heavier elements will be examined in further papers of this series.

Considerable attention has been given to the generation and assembly of high quality fundamental data in support of the GCR modelling. Also datasets of fundamental and derived data have been specified precisely, and codes have been organized following the principles of the ADAS Project. The product of the study is the preferred ADAS data for the light element ions at this time.

Acknowledgments

The atomic data and analysis structure, ADAS, was originally developed at JET Joint Undertaking.
